Abstract

In markets with private options, the optimal level of public provision may require balancing a tradeoff between reducing private options’ market power with the possibility of crowding out potentially high-quality products. These considerations are particularly relevant in many developing countries’ education systems where private schools capture high market shares while public schools are overcrowded. We study the equilibrium effects of public provision in the context of a large expansion of public schools in the Dominican Republic. Over a five-year period, the government aimed to increase the number of public school classrooms by 78%. Using an event study framework, we estimate the effect of a new public school on neighborhood outcomes and competing private schools, where we instrument for how quickly the public school construction project finished with the characteristics of the contractor randomly as-

signed to build the project. We find that a new public school increased public sector enrollment significantly. As public enrollment increased, a large number of private schools closed while the surviving schools lowered prices and increased school quality. To study how the level of public provision affects the overall level of quality in the market, we specify and estimate an empirical model of demand (students choosing schools) and supply (schools choosing whether to enter, stay open and what price to charge). We use the model estimates to calculate the level of public provision that maximizes learning. Due to equilibrium competitive effects, we find that the optimal level is non-monotonic in the quality of the increased public schooling.

1 Introduction

Many industries – healthcare, energy, education, etc. – include a combination of public and private entities, and even within-industry, governments have chosen different ways to organize these markets, ranging from full privatization to public-private partnerships to direct public provision. Public provision may ensure equal access to important social services while also investing any extra revenue back into the system, while private provision may prove more efficient if profit incentives lead to more innovation or higher quality. Further, the sectors may interact and exert competitive pressure on each other, though at the risk of crowding out high-quality unsubsidized options. In this paper we study the optimal level of public provision in primary and secondary education with a focus on how changes in public provision affect equilibrium levels of competition.

These issues are particularly relevant in low-income countries where state capacity to deliver services may be limited. Across many countries and large cities in Latin America, private schools capture large market shares (Figure 1). And because in many cases private options are not subsidized by the government, this could indicate that they are providing higher quality instruction. Yet, many countries’ public school systems are overcrowded such that seats or hours in the public sector are rationed. Thus, the private sector may be only a temporary substitute for too little public provision. Whether private schools out-compete public schools on quality or space is important for designing optimal policy. Indeed, a higher quality private sector might encourage less public provision (and perhaps more public financing of private options) while a private sector that gains market share by having excess capacity might lead governments to expand public provision.

Separating these channels and more generally understanding how the public and private sectors interact is difficult because private provision is determined in equilibrium and may respond to public policies. In this paper, we therefore leverage a large investment in public school infrastructure in the Dominican Republic (DR) that increased government spending on education from 2.5% to 4% of GDP in a single year. This 78% expansion of public capacity allows us to examine the effects of public provision on a student’s choice of sector and learn whether initially high private sector shares reflected insufficient public provision. Further, because the initial equilibrium involved a large private school enrollment share reaching close to 40% in urban areas, the policy effects of the public school expansion likely depend on the impacts on and responses by the private sector. We thus evaluate how the public expansion changes the market equilibrium in terms of which private schools are open.
and what characteristics they operate with.

To answer these questions, we collect data from a variety of sources. We combine administrative enrollment and test score data that is linked to individual students over time with administrative data on eligibility for public benefits and household demographics. We also use administrative data on private schools that includes their prices and investments, variables that are typically not available in administrative data in many countries. To further understand students’ choices and how they depend on school characteristics, we bring in detailed data from surveys of students and principals.

We identify the policy effects by exploiting details of the procurement process. The projects were assigned in four waves, and in each wave the government held a lottery to determine which contractor would execute which project. These lotteries induced substantial entry among contractors such that over 80% of potential builders did not yet have a construction firm. We thus use the randomized assignment of projects to contractor types – specifically, whether the randomized builder is a firm, the builder’s pre-lottery log employment and log employee-months – as instruments that led some projects to finish faster than others. This exogenous variation lets us compare local areas all designated to receive a new public school but for which the year the school opened varied for reasons orthogonal to area characteristics.

We embed such variation in an event study framework and estimate the impact of a new public school on a variety of outcomes. We start by showing that the new public schools enrolled large numbers of students such that incumbent schools saw a substantial decrease relative to pre-policy levels. To further understand the sources of these enrollment shifts, we assess whether the private schools were affected by – and how they responded to – the new schools. We see that private schools near new public schools saw a large decrease in enrollment, much of which came in the form of private school closures. Among private schools that remain open, we see a decrease in the prices they charge, and an increase in test score value-added.

These results imply that much of the policy impact may have been mediated through effects on the private schooling sector. How these changes affect overall quality is potentially non-monotonic. The increased competitive pressure raises school quality, while the crowd out of (unsubsidized) private schools has an ambiguous effect on available quality. To understand the optimal level of public investment, given this potential tradeoff driven by supply side responses, we extend the analysis by estimating a structural model of demand and supply. In the demand model, students choose a school for 9th grade based
on the school’s characteristics and the student’s heterogeneous preferences. On the supply side, schools maximize profits by choosing whether to enter the market, price, and whether to remain open. As schools operate in a large but highly differentiated market with many competitors, predicting the strategic responses of all relevant competitors is a high-dimensional problem, especially given the discreteness of the entry and exit choices. We thus make a behavioral assumption on how schools assess their competition. We use a notion of a static “oblivious” equilibrium as introduced in Sánchez (2018). Essentially, schools keep track of the expected (exponentiated) value students receive from attending a competing private school. This behavioral assumption, with consistent beliefs, yields an equilibrium that simplifies computation.

We estimate the demand model via simulated method of moments. We use aggregate enrollment share moments supplemented by several sources of exogenous variation. Specifically, we use same builder characteristics from the event study analysis. We also leverage the increased hours offered by the public school system as a shock to competition. We further construct micro moments from survey data that ask students what school they would choose if (1) their preferred school were not available or (2) if all schools had zero prices. These responses to hypothetical choice scenarios reveal significant information about preference heterogeneity and how students trade off price versus other characteristics.

On the supply side, we assume optimal price-setting to maximize (perceived) profits. This allows us to invert price first-order conditions at the observed price levels and back out marginal costs. We find that most schools have significant market power in pricing, capturing nearly all revenues as variable. But our estimates of the fixed cost distribution indicate that total profits are quite low, not surprising given the large exit response to the new public schools.

With our estimated model, we revisit our question of the optimal level of public provision. We consider the government’s problem as choosing the amount of public provision (schools) to maximize student learning, subject to a technological constraint that determines the quality of the new schools.¹ To explore this problem, we conduct counterfactual exercises that vary the level of public provision, and at different levels of quality. Our benchmark estimates vary the level of public provision holding fixed the quality at the low levels observed in the schools that opened under the construction initiative.²

¹Future drafts will incorporate the financial cost of provision.
²The new schools have mean value-added of −0.06 student standard deviations (σ), the incumbent public schools have mean value-added of −0.02σ and the private schools have mean value-added of 0.002σ.
We explore the consequences of varying the level of public provision from a low level – matching the pre-construction level in the DR – all the way to an expansion three times as large as the actual construction initiative. We find that the private school exit rate is fairly unresponsive to increases in public provision at low levels, but then around the size of the actual policy, exit rates quickly double and increase steadily for bigger levels of public provision. Prices follow an opposite path, starting high but then dropping once public provision expands. We evaluate the effect on student learning – which is ex-ante ambiguous – and find that learning (as measured by enrollment-weighted market mean value-added) falls for small expansions in public provision before raising once the expansion is a bit larger than the actual policy. It peaks just before a three times policy before falling slightly. This non-monotonicity reflects several forces – students switching to the new public schools that tend to be lower quality, high-quality private schools lowering prices and attracting more students, and crowd-out of private schools, starting with low-quality but then affecting some high-quality schools.

We end by characterizing how the optimal level of public provision varies with the technology (quality) of the new public schools. While higher quality new schools tend to lead to equilibria with more student learning, this is not always the case. At very high levels of provision, the high quality public schools crowd out enough high quality private schools that learning actually falls (relative to lower quality provision). Further, the relationship between learning and the amount of public provision varies depending on the quality level. While lower quality provision produces more learning at higher levels of provision (near three times the observed policy), the optimal level of higher quality schools is closer to two times the observed policy. These non-monotonicities highlight the importance of considering equilibrium responses when choosing levels of public provision.

1.1 Related Literature

This paper relates to several large literatures. The first strand examines interactions between public and private schools and has focused on whether school quality responds to competition (e.g., Hoxby (1994), McMillan (2005), Card et al. (2010), Neilson (2013)) and how students sort between the public and private sectors (e.g., Hoxby (2003), Epple et al. (2004)). The second strand evaluates school funding reforms and whether spending affects student outcomes. Work on school funding reforms and effects on private school enrollments

3The current literature review is highly incomplete and will be extended in the next draft.
includes Downes and Schoeman (1998), Hoxby (2001), and Estevan (2015). This paper also builds upon Dinerstein and Smith (2018) by adding intensive margin private school responses.

2 Background and the School Construction Program

The Dominican Republic has seen the fastest economic growth of any Latin American country over the last two decades, at an average rate of 5.3 percent per year (World Bank, 2018). Education access has improved in line with this growth, with gross enrollment rates of 102 percent at the primary level and 77 percent at the secondary level (World Bank, 2018). But while more students have enrolled in school, the system’s public capacity had been limited, such that most students either attended an oversubscribed public school that divided students into shifts or a private school. Perhaps related, education outcomes lagged behind other countries, as reflected by the Dominican Republic claiming last place in student skills among all participating countries in the international TERCE in 2013 and PISA test in 2015 (UNESCO, 2015; OECD, 2016).

2.1 The School Construction Program

Improving educational outcomes became an important issue in the 2012 presidential election, and Danilo Medina won with a promise to allocate 4% of GDP to education. Figure 2 shows a dramatic increase in the share of GDP allocated to education from 2.5% in 2012 to 4% in 2013. This allocation has been used primarily to finance school construction and renovation for two flagship education programs: Jornada Escolar Extendida (JEE) and Quizqueya Empieza Contigo (QEC). JEE is a program to transition the country from a half-day schooling model to one of full-time schooling, intended to broaden educational offerings and improve performance on pedagogical management indicators. QEC is an early childhood development (ECD) program tasked with increasing the coverage and quality of services provided to children between 0 and 5 years of age, based on the notion that the

---

4 The primary gross enrollment rate above 100 percent reflects the high prevalence of over-age enrollment.

5 TERCE is an international standardized examination that compares student learning among Latin American countries.

6 The initial budget allocated more than 2.5 billion dollars to infrastructure.
nature of learning is cumulative (Shonkoff and Phillips, 2000) and that environments that do not stimulate young children place them at an early disadvantage (Heckman, 2006).

In November 2012, the government issued Decree Number 625-12, which created the National School Construction Program (Programa Nacional de Edificaciones Escolares, PNEE hereafter). The PNEE mandated the construction of 28,000 classrooms across primary and secondary schools over a four-year period, which would be needed to meet the demands of full-time schooling under the JEE. Prior to the reform, school buildings functioned in two or three shifts to accommodate high student demand. In 2012, about half of the public enrollment attended a morning shift, while just 2% of public enrollment was in full-time instruction.\footnote{The matriculation shares by shift are: 49\% to morning shifts, 44\% to evening, 5\% to night, and 2\% to full-time school days.}

The expansion required to move away from the multiple shift model – without overcrowding – corresponds to a 78 percent increase in the number of classrooms available in 2013. To achieve this goal, 425 schools were refurbished or expanded, and over 1,300 new schools were built. An additional 100 new ECD centers built to satisfy the needs of QEC. This represents an increase of 87\% relative to the 114 ECD centers that existed in 2013.

2.1.1 Construction Lotteries

The years leading up to the PNEE saw several corruption claims related to the procurement of school construction contracts. Cases were brought to court in which the government paid selected firms 20 percent of the value of awarded contracts in advance and, subsequently, the construction of many schools was severely delayed or never begun. To promote procurement transparency in the aftermath of these corruption cases, the government decided to allocate new school construction contracts for the PNEE and QEC through open lotteries carried out by the Office of Procurement Services and the Ministry of Education. Civil engineers, architects, and construction companies fulfilling certain minimum requirements were invited to participate in the lotteries, either as firms or as individuals.

School construction, expansion, and renovation projects were grouped into lots to be drawn together and allocated to a single firm or individual through the lottery process. Lots had different budgets determined by the number of classrooms they included. Each lot could only involve construction work related to one school. Overall, 1,833 lots of construction contracts for the PNEE and QEC were allocated through lotteries between 2012 and 2014.
These lots were then drawn through four different lottery waves for the PNEE and one lottery wave for QEC, for a total of five lottery waves. See Appendix A for more details on the lottery assignment.

2.2 Urban markets in the Dominican Republic

The private sector is a key actor in the primary and secondary school sector in the Dominican Republic, especially in urban markets where it accounts for more than 30% of total enrollment. Accordingly, nearly 70% of private schools are located in these areas. Private schools are usually independently run and tend to be smaller, with a median per-grade enrollment of 40 students compared to 147 in public schools. In contrast to some other countries in the region, private schools are not subsidized via vouchers and their tuition fees translate one-to-one to out-of-pocket expenses from parents. The average private school charges $650 yearly for secondary grades, and must attract enough students to cover costs. Private schools prices are transparent, as they are reported to the government; there is minimal use of price discrimination.

3 Data

We combine several datasets to characterize the schools and student population affected by the expansion policy and to determine its impact along several margins and outcomes of interest. We use census data together with records from a nation-wide conditional cash transfer program to define schooling markets and to characterize the population served by primary and secondary schools. We also have access to detailed administrative education data including enrollment records of the universe of primary and secondary schools linked with students’ performance on the national high-school exams (PN), which we use to create measures of enrollment and quality of schools. We combine these data with administrative records from private school prices and investment strategies. We use detailed data from the school construction program to track the construction progress and inauguration status of every new public school in every educational markets in the country. Finally, we complement our data with in-depth surveys to parents, students, and school principals.

8Private schools account for a 23% and 25% of primary and secondary schooling enrollment, respectively.
3.1 Census and Conditional Cash Transfer Program:

*Census:* We have access to the Census micro-data from 2010. We leverage the granularity and geographic nature of these data to create geographic schooling markets. We classify the population into two groups, according to educational attainment: less than high school or at least some high school. Combining this measure with population counts, we are able to characterize every educational market in terms of size and educational demographics.

*Conditional Cash Transfer Program:* Prosoli is a conditional cash transfer program that provides families with income conditional on the school attendance of the children in the family. We have access to the universe of beneficiaries of the program. We use this dataset with two goals. First, we merge household locations to Census data to quantify the share of prosoli beneficiaries in each of the markets, and use it as an income proxy. Second, this data contains detailed information on school-choice of every individual in the program, that we use to construct micro-moments that we use for demand model estimation.

3.2 Schools and Students

*Enrollment:* We use administrative school enrollment data for all students from the 2010 to 2019 school years. This dataset is provided by the Ministry of Education and contains information on every student enrolled at any primary or secondary education institution in the Dominican Republic. We have access to student identifiers that allow us to track individuals over time and across schools, and to link them to other data sources. In addition to the student level data, we also observe school characteristics such as its location, district, sector (private or public), and the shifts they serve (morning, afternoon, or evening). We use these data to construct a panel of aggregate enrollment by school and grade level over time.

*National Examinations:* We have access to the universe of students taking national exams (*Pruebas Nacionales* - PN hereafter) since 2010. These examinations were mandatory for promotion for 8th graders until 2016, and are still required for 12th graders. The data includes students’ course GPA and standardized exam scores. We link these data to the enrollment records to create value-added measures for every high school in our sample. In 2016 the research team included a short questionnaire to the universe of students taking

---

9Unless indicated otherwise, we refer to school years by their spring year – e.g., 2012 for the 2011-2012 school year.
PN that allows us to recover the education of their parents as well as other individual characteristics.

Private Schools: Every year, the Ministry of Education surveys private schools to keep track of their pricing and expenditure strategies. The principal of the school is requested to report the posted prices for each of the grades offered by the school, as well as the expected tuition fee for next year. In addition, private schools need to report the investment they are expecting to make to justify the price increases. The investment form is broken down by infrastructure, equipment, teacher training, labor conditions of teachers, and administrative staff.

In-depth Surveys: We performed in-depth surveys to student and principals from both private and public schools. We use this information to construct model moments and to validate our demand and supply model estimates.

3.3 Lotteries and School construction

Construction: We collected information from several stages of the school construction program. In particular, for each construction lot we observe the contractor assigned by the lottery, as well as every other lottery applicant. From the lottery records we observe whether the contractor is a firm or an individual, together with a tax identifier that allows us to match to several characteristics from tax records. We also observe the expected and realized budget for each project, as well as the number of classrooms specified in the original project. Finally, we merge our data to records from the Ministry of Public Works to track the progress of every construction over time. Specifically we observe the initial and final dates of construction, annual construction progress, and the inauguration date of the school.

4 Event Study Analysis

We start the analysis by estimating the causal effect of a new school opening on a variety of equilibrium outcomes. We employ an event study empirical design that identifies effects based on the differential timing of when local areas had a new public school open.

The complexity of the policy – several waves of assignments of new or expanded schools – plus heterogeneous student substitution patterns across schools require some choices in
summarizing the treatment and who might be affected. We first define a school’s “neighborhood” as a 1 kilometer radius around the school. As students travel an average of 1.6 kilometers from home to school, this definition means that neighborhoods contain very close competing schools. The analysis will test for effects of new public schools on students or other schools in the same neighborhood. As distance is just one factor determining students’ choices, we may not perfectly capture exposure to a new public school. But we opt for the transparency of using a simple exposure definition and later explore robustness.

The second choice is how to define the timing of the event. For each neighborhood, we will use the opening of the first new school as the event. Thus, post-event periods may have larger treatment effects both because the impact of the initial new school grows over time and because additional new schools are opening in the same neighborhood.

4.1 Effects on Enrollment

We start by examining whether the new schools changed where students enroll. For school \( j \) in year \( t \), we find the first assigned new public school in the same neighborhood \( n \) as \( j \). Let \( YearInaugurated_n \) indicate when the public school opened and first enrolled students. For some outcome \( y_{jt} \), we specify the following event study model:\(^{11}\)

\[
y_{jt} = \sum_{\tau=-3}^{3} \beta_{\tau} 1\{YearInaugurated_{n(j)} = t + \tau\} + \theta_j + \theta_t + \epsilon_{jt}
\]

If the government assigned new schools according to local (time-varying) educational needs, the year of inauguration may not be orthogonal to neighborhood shocks. Or if assignment were random but smaller schools were built faster than larger schools, yet-to-finish schools would be a poor control group for opening schools. Therefore, we use the details of the public procurement process to construct instruments for when a neighborhood receives a new school. First, because the project assignments were via lottery, the characteristics of the assigned builder are independent of the project characteristics. Second, because so many projects were assigned, many assigned builders were not part of a firm but rather entered the procurement lottery as an individual. We compare project characteristics – budgets upon assignment and updated budgets post-assignment as well

\(^{10}\)At the end of this section, we extend the results to consider larger, non-overlapping neighborhoods according to administrative boundaries.

\(^{11}\)We also use the same specification for neighborhood outcomes \( y_{nt} \) where we include neighborhood instead of school fixed effects.
as the number of classrooms – across projects assigned to firms or individuals, the firm’s log employment, and the firm’s log employee-months. We control for the wave-province in which the project was assigned and use only within-lottery variation. We present the results of these balance tests in Table ??.

We see that the characteristics of the assigned contractor are not statistically related to the project characteristics.

Post-assignment, if firms, based on experience, selection of the best builders, or well-developed supplier networks, are more efficient at building schools, then neighborhoods whose new schools were assigned to firms may receive their finished schools sooner than neighborhoods whose new schools were assigned to individuals. We assess this possibility in Figure 3 where we plot histograms of the number of years between when a new school project was assigned and when it was inaugurated, separately by whether the assigned builder was a firm or an individual. We see overlap – plenty of individuals finish projects quickly – but on average firms complete their projects slightly faster. We present first stage regressions (using just firm status as the builder characteristic) in Table 2. The endogenous regressors are time until or since inauguration while the instruments are whether the project was assigned to a firm, interacted with how many years it has been since project assignment. We see that projects that are assigned to firms are more likely to open two years post-assignment than projects assigned to individuals. This increase of 9 percentage points borrows largely from opening probabilities in the subsequent two years.

Before proceeding to instrumental variable estimates, we consider the exclusion restriction. Building time may not be the only project outcome affected by the assigned builder. In particular, firms may build faster and produce higher quality buildings. If this were the case, we would find it difficult to separately identify the effect of the opening of a homogeneous new school from the effect of a higher quality school. Separately identifying these effects is not necessarily crucial for demonstrating that public provision can have direct effects on students and equilibrium effects in terms of competition. But for interpreting the treatment within our model, we need to take a stand on what variation the builder generates. Here, we rely on the quality inspections that the Dominican government carried out. If school building quality was too low, the inspectors required changes prior to the school opening. This inspection process potentially limits variation in building quality upon opening.

We now present our event study results, using the assigned builder’s characteristics to

\[12\] Employees are typically hired at the monthly level and because the construction industry often offers irregular work, employee-months captures the intensity of labor usage, conditional on annual employment. Employment and employee-months are recorded for firms and individuals who employ others.
generate variation in when a new school opened. In Table 3 we show the estimates for the
effect of a new school on enrollment outcomes. The first column is the enrollment of the
new school. Unsurprisingly, the new school’s enrollment increases once it is opened.\textsuperscript{13} This
increase in new public school enrollment appears to come at the expense of private schools,
as the neighborhood’s number of private schools and their within-neighborhood enrollment
shares both decrease after the new public school opens. The effect on the number of private
schools and private enrollment grow stronger over time.

Additionally, because our neighborhoods are small geographic units, and because some
students are on the margin of dropping out, we test whether the new public school increases
total neighborhood enrollment. Interestingly, we don’t find increases, which could indicate
that school choice is determine primarily by geography. We show the results visually with
event study coefficient plots in Figure 4.

The effect on the number of private schools could come from reduced entry or increased
exit. We therefore run exit regressions where the outcome is whether a school exited in
year $t$ and present the results in Figure 5). Because the exit decisions may be made in
anticipation of schools to open in coming years, the expected timing of the exit response is
ambiguous. We therefore start by modifying our event study specification to define event
time relative to when the lottery was held. Since construction usually took a few years,
the new public schools would not have immediately opened, but private schools might
still make forward-looking exit decisions. But because our instruments shift construction
completion time, conditional on when the assignment lottery was held, we do not have an
instrument for time since lottery and thus run OLS regressions that exploit variation in
timing across lotteries. We see that prior to the lottery, there is little evidence is differential
pre-trends across private schools soon to receive new or expanded public competitors. Then
in the years following the lottery, we see an increase in exit rates. By the second year after
the lottery, the cumulative exit rate is 5% and it increases linearly with each year post-
assignment of the new public school.

Because cross-lottery comparisons may introduce omitted factors affecting private schools
independently of the new public school construction, we return to our instrumental vari-
ables event study analysis and define time relative to when the public school opens. The
estimated coefficients, plotted at the bottom of Figure 5), show a similar pattern to the OLS
estimates using the lottery assignment as the event. Here, we see increases in exit starting

\textsuperscript{13}If all schools were truly “new” we would have no data prior to opening. Many of the new schools are
in fact expansions, so we have pre-period outcomes.
perhaps the year prior to inauguration, but with most of the exits post-inauguration. These event study estimates indicate that the new public schools induced a large reallocation of enrollment toward the new schools and away from the private schools.\footnote{We find little effect on student dropout.} This reallocation has the potential to change private schools’ profits in a way that led to extensive margin responses (exit). But if there are also intensive margin responses to increased competition, these may lead to better student outcomes.

## 4.2 Effects on School Characteristics and Student Outcomes

To assess the effect on school characteristics beyond enrollment, we must condition on a school being open. We therefore have variation only within neighborhoods that have private schools (if the characteristic is specific to private schools). This sample restriction costs us considerable statistical power. Thus, we alter our empirical analysis in three ways. First, we use a broader neighborhood definition to include more schools, at the possible downside of including weaker competitors. We define a “neighborhood” as the Census’s administrative unit of a “barrio/paraje.” These neighborhoods vary somewhat in size with a mean area of 3.8 square kilometers throughout the country but 0.7 square kilometers in urban areas.

Second, we center the analysis around the private schools such that an observation will be a school $j$ in year $t$. This allows us to incorporate school fixed effects, which soak up time-invariant heterogeneity. Third, we drop our instrumental variables strategy and instead refine the time fixed effects to vary with the new public school’s assignment lottery wave, $l$. We therefore estimate the event studies assuming within-lottery variation in when a school opens is orthogonal to time-varying local schooling outcomes (except through the presence of the new school).\footnote{For the price outcomes, our instrumental variable estimates are often sufficiently precise to reject the null of zero effect. In these cases the instrumental variable estimates qualitatively align with the OLS estimates.} Specifically, we estimate:

$$ y_{jt} = \sum_{\tau=-3}^{3} \beta_{\tau} 1\{YearInaugurated_{j} = t + \tau\} + \theta_{j} + \theta_{lt} + \epsilon_{jt} $$

We start by examining private school prices in Figure 6. Dominican private schools typically charge both an annual enrollment fee and then a monthly fee. We see modest price drops in monthly fees following the opening of a new public school, with secondary...
school annual enrollment fees and monthly charges each falling by about 10% of the average level. These price drops could reflect reduction in market power but could also entail less spending on productive inputs that generate learning outcomes. In Figure 7 we present event study results for the effect of the new public school on test score value-added.\textsuperscript{16} Immediately upon inauguration of a new public school, we see a moderate increase for grade 12 value-added of over 0.07σ for private schools. We do not see any corresponding increase for local public schools’ value-added.

Private schools may achieve test score increases by providing better quality instruction or by selecting higher achieving students. This could be particularly likely in a context, like this, where there is a large enrollment reallocation across sectors. In Table 4 we test for changes in sorting of students by sector. For each high school, we calculate the mean 8th grade test score of its 9th grade entering cohort. These tests were taken when the students attended a different school for primary education and thus are not subject to mechanical changes from improvements in private high school instruction. Our estimates are somewhat noisy, but we do not find any strong evidence that students are changing how they sort to sector, at least according to past test scores. Thus, it appears that the reduced revenue may reflect reduction in market power rather than lowering quality.

Another margin of competition could be in school hours. We thus test whether private schools increased the length of the school day to compete with full-day public schooling. In Figure 8 we see that while the number of public school hours increased with the new schools, private schools did not adjust. Private schools go from offering more hours on average before the school construction policy to offering fewer after.

In summary, we find that the new public schools had large impacts on the market. They increased public sector enrollment, which led to private schools either closing or lowering their prices and increasing their quality.

\textsuperscript{16}As is standard in the education literature, we standardize test scores into z-scores based on grade-year means and standard deviations. Thus, a 0.1 coefficient reflects a change by one-tenth of a student standard deviation. We construct value-added by residualizing the mean of a student’s math and Spanish scores with cubic polynomials in the student’s subject-specific eighth grade scores, the student’s gender, a polynomial in the student’s age, and school characteristics including the type of session the student attended.
5 Empirical Model

The event study analysis demonstrates that the new public schools affected student outcomes by changing the schooling market equilibrium. To isolate the impacts of each mechanism and to conduct counterfactual policy analysis, we specify an empirical model of student choice in secondary education (demand), school pricing, entry and exit (supply), and value-added (technology).

In each school year $t$, the schooling economy exists of a set of 9th grade students indexed by $i = 1, ..., I_t$ and sets of potential schools indexed by $j = 1, ..., J_t$. We let $j = 0$ represent the option of not attending any school. Each student and school belongs to a market $m$. Let $I_{mt}$ and $J_{mt}$ denote the set of students and schools, respectively, in market $m$ in school year $t$.

5.1 Educational Markets

Defining the market is a difficult task in many settings when physical distance is a relevant characteristic. It is generally not easy to find a boundary where one market ends and another begins in broad urban areas. Papers that study retail markets typically have used political or administrative boundaries to define markets such as cities or counties (Davis, 2006). In some cases, such as small isolated communities, this works well. However, in large urban areas consumers close to the border of a county might also be close to firms in the next county. In these cases, it is possible for consumers to choose to cross market lines to buy from firms in neighboring markets. In this application, we follow Neilson (2013) and take advantage of the relatively sparse distribution of the population in the Dominican Republic where communities tend to be far from each other. This creates a natural definition of a market based on the idea that consumers in one city will not travel very far across rural areas to go to school in another city.\footnote{In principle, we could forgo separating students and schools into markets and estimate a single equilibrium. But dividing the country into markets yields considerable savings in computational time.}

We define a schooling market $m$ as follows:

1. Geographic boundaries $B^m$ (a polygon).

2. A set of schools $J^m$ that operate within $B^m$ at any point in time.

3. A set of $I^m$ students of $K$ observable types that live inside the market.
4. A distribution of student types across markets. The distribution is described by $\Pi_m$ which is a vector of length $K$ containing the shares of each type of student in the market $m$. We have that $\sum_k \Pi_m^k = 1$ for each market $m$ and $\sum_k S_k^m = S^m$.

5. A set of $N^m$ nodes spread evenly within the boundaries of the market that describe where students are located.

6. A distribution of student types across nodes within each market. This distribution is described by $w_m^k$ which is a vector of length $N^m$ containing the share of students of type $k$ of the market $m$ that are located at each node $n$. We have that $\sum_n^N w_{nk} = 1$ and $\sum_k^K \sum_n^N w_{nk} \Pi_k^m S_k^m = S^m$

We use neighborhoods from the 2010 Census (BPs hereafter, for Barrio/Paraje) as the building blocks of our markets since they are small enough to be entirely classified as either urban or rural. The average BP has an area of 3.8 $km^2$ and is populated by 250 households. For our analysis, we define a BP as urban if the neighborhood meets any of the two restrictions: i) an urban BP as classified by the census, or ii) population density of over 1000 inhabitants per $km^2$. Figure 9 highlights all the selected urban BPs. The mean area of the selected neighborhoods is 0.7 $km^2$.

Next, we proceeded to join all urban neighborhoods that were separated by 2 $km$ or less at their closest distance. This resulted in 302 non-overlapping markets that could comprise a single neighborhood (isolated urban areas) or any number up to 272 neighborhoods. Around each market, we added a 1 km buffer. Figure 10 shows an example of the market of Santo Domingo. After defining the market boundaries, we overlay a grid of squared nodes on top to have a standardized geographic unit that is consistent over time. The nodes are 400m $\times$ 400m and thus have an area of 0.16$km^2$.

For each market we recover the number of households and total population from Census 2010 data. We combine it with Prosoli data to recover the number of poor individuals in the area. The population of the markets is binned into 4 groups (based on 2 levels of educational level attained interacted with poverty status) that may predict heterogeneous responses to the policy in place. In Appendix B we explain in greater detail the markets definition and the linkage of the different datasets.
5.2 Demand: Student Choice of School

Ninth grade students are heterogeneous in their observable characteristics and preferences. Students’ observable characteristics are whether their family qualifies for the Prosoli program $x_{it}^p$, the education level of their mother $x_i^e$, and their residential location $l_{it}$. Prosoli eligibility is a binary status while we segment mother’s education level to be binary as well (0 if mother completed at most primary school, and 1 if mother attended secondary school or more). Students’ unobservables preferences are the vector $\nu_i$.

Students choose a single school to attend (or dropout) under an open enrollment system where we assume capacity constraints do not bind. Schools are differentiated in terms of their price $p_{jt}$, value-added $VA_{jt}$, hours of instruction $hr_{jt}$, whether they are private $priv_{jt}$, a location $l_{jt}$, and an unobservable (to the econometrician) $\xi_{jt}$. Let $dist_{ijt} = d(l_{it},l_{jt})$ where $d()$ is the geodetic distance function.

Student $i$’s utility from attending school $j$ in school year $t$ is:

$$u_{ijt} = -\alpha_i p_{jt} + \beta_i^{VA} VA_{jt} + \beta_i^{hr} hr_{jt} + \beta_i^{priv} priv_{jt} - \gamma dist_{ijt} + \xi_{jt} + \epsilon_{ijt}$$

with $u_{it0} = \epsilon_{it0}$ representing the utility from not attending school (dropping out).

We specify the preference coefficients as:

$$\beta_i^{VA} = \bar{\beta}^{VA} + \beta_1^{VA} x_{it}^p + \beta_2^{VA} x_i^e + \beta_3^{VA} x_{it}^p x_i^e$$

$$\alpha_i = \bar{\alpha} + \alpha_1 x_{it}^p + \alpha_2 x_i^e + \alpha_3 x_{it}^p x_i^e + \nu_i$$

where $\nu_i \sim iid \ logN(\mu_\alpha, \sigma_\alpha^2)$. We let $\epsilon_{ijt} \sim iid \ T1EV$.

5.3 Supply: Private School Entry, Exit, and Pricing

We assume that public schools are non-strategic; i.e., their supply (and characteristics) are determined exogenously by government policy. In a first stage, we model location-specific potential entrant private schools as deciding whether to pay an entry cost and enter the market. In a second stage, we model new entrants and incumbent private schools as simultaneously choosing whether to remain open and what price to charge to maximize

\footnote{In our principal surveys, most schools report finding space for a student even if already at capacity.}
profits.\textsuperscript{19} We treat this choice as a static problem such that schools make choices to maximize this year’s profits only.

We describe the schools’ actions in stages and refer to the timeline in Figure 11 for help in exposition. At the beginning of the year, schools’ exogenous characteristics ($VA_{jt}$, $hr_{jt}$), demand unobservable ($ξ_{jt}$), marginal cost ($mc_{jt}$), and fixed operating cost ($FC_{nt}$) are drawn.\textsuperscript{20} Other than the fixed operating cost, these characteristics are public information to all schools. $FC_{nt}$ is drawn from a known distribution $G$ and varies by location ($n$). Thus, two schools in the same location have the same fixed operating cost. Each school knows its own location’s fixed cost but only knows that other locations’ fixed costs are drawn from $G$. Thus, the information set at time 0, $Ω_{0j}$, consists of ($\vec{VA}, \vec{hr}, \vec{ξ}, \vec{mc}, FC_{n(j)t}$).\textsuperscript{21}

Armed with information $Ω_{0j}$, a set of potential entrants decides whether to pay the entry cost, $χ$, to enter the market. This entry cost includes registration fees and any costly learning of how to run a school. We allow for free entry at all locations in the market, such that each location has a potential entrant every year. The assumption of free entry reflects the nature of the Dominican urban private schools. Many of these schools are run out of the school leader’s home, and often the school leader gave up a for-profit business unrelated to education to start the school. These features lead to a large number of locations to hold a school plus the large pool of potential school leaders. The potential entrant’s decision is:

$$\max_{Enter_{jt}} Enter_{jt} \cdot \left( E_{θ_0} \left[ \tilde{Π}_{jt} \right] - FC_{nt} - χ \right) \quad (2)$$

Note that we place modifiers over the variable profit, $Π$. These reflect beliefs and behavioral assumptions, which we will return to once we describe the other stages. We draw the potential entrants’ characteristics from the incumbents’ distribution of characteristics; in future drafts, we plan to estimate differences in these distributions.

After the first stage, entry decisions are realized and observed by all market participants. When observing which locations have added an entrant and which locations have not, schools update their beliefs on the distribution of others’ location-specific fixed costs.

\textsuperscript{19}Unlike private schools in the US and other countries, Dominican private schools are usually for-profit entities. Most schools do not have religious or other affiliation that might lead to alternate objectives.

\textsuperscript{20}In future drafts, we hope to relax this assumption and, in particular, allow private schools to make endogenous investments that shift their value-added.

\textsuperscript{21}This choice to have marginal costs be public information but fixed costs be private information reflects the government’s regulation of private schools which requires schools to report their prices, as well as any changes to costs that affect prices. The gathering of such data into a public database potentially allows schools to observe each others’ marginal costs.
Concretely, schools calculate \(E_{\Omega_0}\left[\hat{\Pi}_{jt}\right] - \chi\) for each potential entrant and use this to bound \(FC_{nt}\) from above if entry occurred and from below if entry did not. Thus, the information set for at \(\tau = 1\), \(\Omega_1\) includes everything in \(\Omega_0\), plus knowledge of the set of competitors and bounds on other locations’ fixed costs. This belief updating captures the idea that market participants likely have some information about other locations’ costs, and it will be important when we take the model to data in summarizing geographic heterogeneity.

In the second stage, the entrants and incumbents choose whether to exit and, if not, what price to set. For market size \(N_{mt}\), schools choose price and whether to exit:

\[
\max_{\text{Exit}_{jt}, p_{jt}} \left(1 - \text{Exit}_{jt}\right) \cdot \left[\left(p_{jt} - mc_{jt}\right) \cdot N_{mt} \cdot E_{\Omega_1}[s_{jt}(\vec{p}, \vec{VA}, \vec{hr}, \vec{\xi})] - FC_{nt}\right]
\]

where their perceived enrollment, as a function of price and other characteristics, is \(N_{mt} \cdot E_{\Omega_1}[s_{jt}(\vec{p}, \vec{VA}, \vec{hr}, \vec{\xi})]\).

Because schools do not know each location’s fixed cost exactly and choices are made simultaneously, schools must predict the enrollment they would get as a function of their own decisions. A natural choice would be for schools to maximize expected enrollment, \(N_{mt} \cdot Es_{jt}\), where the expectation is taken over other schools’ fixed cost distributions. But because markets can include many schools, this expectation is over such a high-dimensional space that we consider it unlikely schools are sophisticated enough to make such a calculation. An alternative would be to have schools only consider their close neighbors’ fixed cost distributions. Schools, however, have overlapping sets of neighbors such that even change in schools far away could shift the demand for a local school.

We instead make a behavioral assumption that simplifies the school’s problem while preserving much of the strategic considerations of competing against products with varying degrees of differentiation. We follow Sánchez (2018) by assuming that schools keep track of their own type (fixed cost draw), bounds on the other locations’ fixed costs, and the expected market equilibrium.\(^{22}\) Specifically, let \(V_{ikt} = u_{ikt} - \epsilon_{ikt}\) be student \(i\)’s utility, without the \(\epsilon_{ikt}\), to attending school \(k\) if the school is open and \(V_{ikt} = -\infty\) if closed. Then let

\[
\lambda_{ijt} = E_{FC_{-n,t}} \sum_{k \neq j, k \text{ private}} \exp(V_{ikt})
\]

be the expected total \(\exp(V_{ikt})\) over all other private schools, where the expectation is over

\(^{22}\)In future versions, we will pursue a hybrid approach that has schools keep track of their own type, their 5 closest neighbors’ types, and the expected equilibrium in a “fringe.”
the other schools’ fixed cost distributions (or, the probability other schools will be open). With our Type I Extreme Value assumption on \( \epsilon_{ijt} \), the perceived probability that student \( i \) chooses private school \( j \) in school year \( t \) is:

\[
\tilde{P}_{ijt} = \frac{\exp(V_{ijt})}{1 + \exp(V_{ijt}) + \sum_{k \text{ public}} \exp(V_{ikt}) + \sum_{k \neq j, k \text{ private}} \exp(V_{ikt}) + E_{FC_{-j,t}} \sum_{k \text{ private}} \exp(V_{ikt}) + \lambda_{ijt}}
\]

(5)

This vector \( \lambda_{ijt} \) has a separate element for each student, which allows schools to consider carefully the heterogeneity in its potential students. With this perceived probability for each student, the school’s perceived quantity of students is \( N_{mt} \cdot s_{jt} = \sum_i \tilde{P}_{ijt} \). This is the share function that the schools’ use when deciding whether to enter and then the optimal pricing and exit decisions.

For schools that decide to remain in the market, they incur the fixed cost, \( FC_{nt} \). Then, given the set of schools that have decided to be open and their characteristics (including price) student’s choose their most preferred option. At this point, school enrollments are realized and private school \( j \) earns its variable profits, \( \Pi_{jt} \).

We return to the entry stage and clarify why the “hat” is above perceived profits. Potential entrants, when deciding whether to enter, consider the competitive environment they will enter and how their own entry choice may affect the equilibrium. In particular, they predict the second stage pricing and exit equilibrium, were they to enter. They also account for the fact that if they enter an already-occupied location, both schools will know each other’s fixed cost with certainty. But to avoid assuming the potential entrants can solve an incredibly complex problem, we impose a restrict on the degree to which potential entrants are forward-looking. We assume that potential entrants do not consider how other potential entrants would shift the second stage equilibrium if they were to enter. This means that potential entrants do not integrate over the possible sets of other entrants – and the associated changes they would cause to other schools’ beliefs – when deciding whether to enter. This assumption allows for the possibility of regret in entry, where a potential entrant is surprised that so many other potential entrants choose to enter and realized profits are below predicted profits.
5.4 Technology: Value-Added

We model the school’s technology in producing learning outcomes as evolving exoge-}

nously. Following the literature, we define a school’s value-added ($\mu_{jt}$) as the school’s causal}

effect on test scores in school year $t$ controlling for a flexible function of past test scores:

$$
y_{12i} = \beta_{VA1} y_{8i,t-4} + \beta_{VA2} (y_{8i,t-4})^2 + \beta_{VA3} (y_{8i,t-4})^3 + \beta_{VA4} + \mu_{jt} + \nu_{it} \quad (6)
$$

where $y_{12i}$ is student $i$’s 12th grade test score in year $t$ and $y_{8i,t-4}$ is student $i$’s 8th grade test score in year $t - 4$. Because students in the Dominican Republic do not take annual tests, we control for scores from 8th grade. We also control for school characteristics, which are omitted from the equation.

5.5 Equilibrium: Static “Oblivious” Equilibrium

A static “oblivious” equilibrium is a set of entry decisions ($Entry_{jt}$ ∀ j potential entrants), prices ($p_{jt}$ ∀ j private), exit decisions ($Exit_{jt}$ ∀ j private), and beliefs ($\lambda_{ijt}$ ∀ i, j private) such that:

1. $Entry_{jt}$ solve 2 for each potential entrant $j$
2. $p_{jt}, Exit_{jt}$ solve 3 for each private school $j$
3. $\lambda_{ijt} = \sum_{k \neq j} (1 - Pr(Exit_k(\lambda))) exp(V_{ikt})$ for each student $i$ and private school $j$ (consistent beliefs).

6 Estimation and Identification

6.1 Estimation

We separately estimate the technology, demand, and supply.

6.1.1 Technology

We start by estimating each school’s value-added for each school year by running OLS regressions of Equation 6 and recovering the estimated fixed effects, $\hat{\mu}_{jt}$.
6.1.2 Household Locations

Students vary according to three observables: whether their household qualifies for Prosoli, mother’s education, and household location. We simulate student observables using the Prosoli and Census data. Specifically, we define a grid with nodes 400m apart and use the Census to estimate the number of households closest to each node and the distribution of mother’s education. We then merge the distribution of Prosoli status onto each node. For more details, see Appendix B.

6.1.3 Demand

We estimate demand using simulated method of moments, where we simulate from the distribution of $\nu_i$. We combine aggregate share moments with instrumental variable moments and micro moments and use a nested fixed point estimation routine as in Berry et al. (2004).

For the aggregate shares, we calculate each school’s 9th grade enrollment share for each market-year using the administrative enrollment data. For the dropout, or outside option, share, we count the number of enrolled 8th graders from the prior year who graduated 8th grade but did not enroll in 9th grade. For each year, we thus have $J_t$ moments. We use these market share moments to recover mean utilities $\delta_{jt} = \bar{\beta}_\mu \tilde{\mu}_{jt} + \bar{\beta}_{hr} hr_{jt} + \bar{\beta}_{priv} priv_{jt} + \xi_{jt}$

in the inner loop.\footnote{Typically $-\bar{\alpha}_p$ would be included in the mean utility. Because we use micro moments to target identification of the price coefficient, we keep it in the outer loop.}

As school pricing decisions likely depend on $\xi_{jt}$, which might also be correlated with $VA_{jt}$, we specify instruments for price and quality. The first set of instruments comes from the policy and match the variation we used in the event study analysis. For each private school, we find the first opening public school in its neighborhood (if there is one) and use the builder’s characteristics as instruments. We use the same characteristics as in the event study analysis – whether the builder is a firm, log employment, whether employment is positive, and log employee-months. The second instrument leverages the school expansion policy’s effect on hours offered at public schools, even those that were not new. Once the new schools started to open, many of the other public schools converted to full-day instruction, on a staggered basis. Thus, even if there were no new public school (yet) in a neighborhood, the incumbent public school may offer more hours of instruction and thus exert competitive pressure on the private school. While a natural response might be
for private schools to adjust their own instructional hours, we do not see much evidence of this. Instead, we allow increased competition through hours to affect private schools’ pricing decisions. We thus construct $z_{jt}$ as the mean number of instructional hours per student offered by public schools in private school $j$’s neighborhood in year $t$. For these instruments, we impose that they are orthogonal to a private school’s unobserved demand shock ($\xi_{jt}$).\footnote{Future versions will incorporate a third price instrument. Public school teacher salaries increased during our sample, and particularly for teachers measured to be high quality. As public and private schools may compete for teachers, private school costs likely increased.}

Finally, we specify a set of micro moments. Using our Prosoli administrative data and the 2016 survey of test-takers, we can match school choices to individual students and their demographics. We construct micro moments for the mean school characteristics (price, quality, private, number of hours) for each demographic group (Prosoli eligibility and mother’s education). We supplement these mean choice characteristics with the mean distance traveled to school from the Prosoli data, which is matched to student residential location.\footnote{Because we place household locations at discrete nodes, we calculate the distance traveled between a student’s assigned node and school attended. The distance is very similar to the household to school distance.} The in-depth student survey asks students what school would be their second choice, after the one they are actually choosing. We use this second choice data to construct covariances in school characteristics (price, quality, private, number of hours) between first and second choices. Lastly, the survey asked students if school prices made them choose a school that is different from the one that they would choose if prices were not an issue. We calculate the change in the probability of wanting to attend a private school if prices were removed.\footnote{In the model, we match this moment by calculating choice probabilities when all schools have 0 prices.} For the survey-based moments, we calculate them within the model using the same populations (e.g., 2016 students for the moments based on the 2016 survey of test-takers).

### 6.1.4 Supply

We specify $G$, the CDF of fixed costs $FC_{nt}$, as:

$$
FC_{nt} \sim \begin{cases} 
\infty \text{ w.p. } p^\infty \\
N(\mu_{FC}, \sigma^2_{FC}) \text{ w.p. } 1 - p^\infty
\end{cases}
$$

\footnote{24}{Future versions will incorporate a third price instrument. Public school teacher salaries increased during our sample, and particularly for teachers measured to be high quality. As public and private schools may compete for teachers, private school costs likely increased.}
We include the possibility for an infinite fixed cost to allow the model, if necessary, to rationalize exits among very high variable profit schools without needing to stretch the fixed cost distribution out so far that it loses its ability to predict exit for smaller profit schools.

We estimate the model with method of simulated moments, where we choose the moments as the event study coefficients (plus the mean exit rate) from Figure 5. With this specification, we estimate the supply model using an adaptation of the iterative procedure described in Sánchez (2018). We start by guessing the distribution of incumbents’ marginal costs and drawing a vector of marginal costs for potential entrants. We then solve for the first stage (potential entry) equilibrium. We use these entry decisions to update beliefs on fixed costs and solve for the second stage exit equilibrium taking prices as given in the data. Once we find the equilibrium, we invert the pricing first-order condition to recover marginal costs for each school in each year.\footnote{Even for many exiting schools we are able to invert the first-order conditions because we observe prices. Our data provides this unique opportunity because many private schools report planned prices for the following school year to the government. In cases where this is not possible, we give schools that exited (without revealing a price) its marginal cost from the prior year.} We then compare the recovered marginal costs to the assumed marginal cost distribution and iterate back and forth between the first and second stages until the marginal cost distribution hits a fixed point. Once we have estimated marginal costs, we estimate the counterfactual equilibrium where no new public schools opened. In this step, we solve for prices and exit decisions, and then we use the model predictions to calculate the moments. In each step where we solve for an equilibrium, we fix \( \lambda \), solve for pricing and exit decisions as a function of \( \lambda \), and then update \( \lambda \) to be consistent with these choices. We iterate until we find a fixed point in \( \lambda \).

### 6.2 Identification

In this subsection, we highlight the sources of variation in the data that prove useful for identifying model parameters. The price instruments exploit policy variation in procurement lottery process and the move to full-day public schooling. The identification assumption is that the neighborhoods most affected by the policy changes did not differ – in terms of the private schools – from the neighborhoods less affected. The randomized lottery used to assign school construction projects to builders provides variation unrelated to local conditions. For the change in public school hours, we assume that the staggered roll-out was unrelated to the local supply of private schools. Additionally, our survey ques-
tion that asks for choices if prices did not matter yields considerable information about how students trade off price and other characteristics. The hypothetical nature of the survey question also provides clean variation in price that holds everything else, including potential equilibrium responses from more standard instruments, fixed.  

The other micro moments map fairly clearly into standard arguments for identifying demand models with heterogeneous preferences. The extent to which students from different demographic groups choose different types of schools pins down preference heterogeneity based on demographics. In terms of the random coefficients, the second choice survey responses are crucial. If unobservable preference heterogeneity for school characteristics is large in magnitude, then we would expect that conditional on mean choice probabilities, covariances in choice characteristics across first and second choices will be high. 

For the supply estimates, our assumption of optimal pricing and the oblivious equilibrium allow us to invert first-order conditions to recover marginal costs. We identify the fixed cost distribution by assuming that the observed exit decisions reflect a trade-off between static variable profits and fixed costs. The event study moments help pin down the dispersion in the fixed cost distribution by forcing many exits even for demand shocks that don’t siphon off all of a school’s students. When we compare the size of the profit shock from the new schools to the difference between potential entrant and incumbent profits (in the case where the potential entrant at the incumbent’s location does not enter), then we determine what fraction of schools would be expected to exit from the profit shock. The entry cost ($\chi$) serves as a shifter of the potential entrant variable profits that allows the gap between potential entrant and incumbent profits to (potentially) widen to match the policy moments. Finally, the probability of an infinite fixed cost is pinned down by the percentage of exits among very high profit schools. 

In estimation, we always find an equilibrium, though we do not have a general existence proof. In terms of equilibrium uniqueness, we have tried multiple starting values and arrived at the same equilibrium but this requires further exploration and we believe it likely that multiple equilibria exist. 

---

28 Because the other price instruments could plausibly lead to changes on the extensive margin of which schools are open, it is possible that $\xi_{jt}$ becomes correlated with the instruments through selection. We therefore will assess robustness to using only the variation from the hypothetical survey question for identifying the price coefficient.
6.3 Estimates

We present preliminary estimates from estimation of our structural model. We start with the demand model (Equation 1) and present the estimates in Table 5. We estimate mean disutilities to distance and price, with a kilometer of distance valued the same as 6 USD in annual tuition. This lack of price sensitivity in preferences is important when considering schools’ incentives to lower prices.

In terms of preference heterogeneity, we estimate a similar price coefficient for all demographic groups, except children with more educated mothers and not prosoli eligible, for whom the price coefficient is less than half as large. For value-added, we estimate a large and precise positive coefficient. We find that the preference is higher for children not prosoli eligible but don’t find large differences based on mother’s education. We also find that students value hours when choosing a school, which is important because the new schools allow the public system to shift to full-day instruction.

On the supply side, we estimate considerable variation in school-year markups of price relative to marginal cost (Figure 12). The distribution of price minus marginal cost (as a fraction of price) is somewhat evenly distributed between 0 and 1, with a median private school having a markup above 40%. Schools are sufficiently differentiated, mainly in space, that they are able to exert quite a bit of market power. Thus, adding another (public) option to students’ choice sets has the potential to induce large increases in competition and lower prices, as seen in Section 4. For the estimated fixed cost distribution, we estimate a mean location fixed cost of 92.5. But because most locations don’t get an entrant (or incumbent), the mean location fixed cost, conditional on having an operating school, is much higher, at 273.0. This could reflect that the best locations, for demand, are also the most expensive. It also means that despite very large markups over marginal cost, total profits are much lower (Figure 13). In fact, over 90% of variable profits are dissipated by large fixed costs.

We estimate no probability of an infinite fixed cost, and the entry cost is just 2.82. This very small level comes because the wedge between potential entrant and incumbent location-specific variable costs is roughly the right size to explain the increased exit rate from the policy.
7 Counterfactuals

With our estimated model, we can conduct several policy counterfactuals that assess how the supply of private schools is affected by the level and type of policy intervention. For each counterfactual, we solve for a counterfactual equilibrium for the year 2018. We take the set of schools open in the data and use the estimated equilibrium $\tilde{\lambda}$ as a starting value in searching for the counterfactual equilibrium. When we vary starting values across a broad range of values for $\tilde{\lambda}$, we always return to the same equilibrium.

7.1 Increased Level of Public Provision

The main counterfactual assesses how private school prices and exit rates vary with the size of the public sector expansion. In addition to providing more options for students, which may increase welfare through any match effects (or, e.g., less distanced traveled) the size of the public sector has direct consequences for the equilibrium supply of private schools. The pro-competitive impact may lead to reduced private school market power and prices, which transfers savings to households and possibly reallocates students toward the (on average) higher quality private sector. On the other hand, expansion of the subsidized sector may crowd out high quality private schools, which might lower student outcomes.

For different levels of public sector expansion, ranging from the no expansion (0) to the observed expansion (1) to three times as big (3), we present the counterfactual private school mean prices and annual exit rates in Figure 14. We find that the private school exit rate is fairly unresponsive to increases in public provision at low levels, but then around the size of the actual policy, exit rates quickly double and increase steadily for bigger levels of public provision. This largely reflects a mass of small schools with relatively high fixed costs whose supply is particularly sensitive to moderate changes in market conditions. Once these schools have exited, the remaining schools are slightly less subject to exit risk. Prices follow an opposite path, starting high but then dropping once public provision expands.

We evaluate the effect on student learning – which is ex-ante ambiguous – and find that learning (as measured by enrollment-weighted market mean value-added) falls for small expansions in public provision before raising once the expansion is a bit larger than the actual policy. It peaks just before a three times policy before falling slightly. This non-

\footnote{We place new public schools in the same locations as the observed expansion and scale the size of the public provision in utility terms.}
monotonicity reflects several forces – students switching to the new public schools that tend to be lower quality, high-quality private schools lowering prices and attracting more students, and crowd-out of private schools, starting with low-quality but then affecting some high-quality schools.

7.2 Varying the Public Technology

We end by characterizing how the optimal level of public provision varies with the technology (quality) of the new public schools. In Figure 15 we plot the learning outcomes for different levels of public provision, by quality of the new public schools. The “Low” technology reflects the observed value-added of the new public schools in the data. The “High” technology corresponds to new public schools that are the same quality as the mean private school, while the “Mid-high” technology is equivalent to the quality of the old public schools that operated prior to the expansion.

While higher quality new schools tend to lead to equilibria with more student learning, this is not always the case. At very high levels of provision, the high quality public schools crowd out enough high quality private schools that learning actually falls (relative to lower quality provision). Further, the relationship between learning and the amount of public provision varies depending on the quality level. While lower quality provision produces more learning at higher levels of provision (near three times the observed policy), the optimal level of higher quality schools is closer to two times the observed policy. These non-monotonicities highlight the importance of considering equilibrium responses when choosing levels of public provision.

8 Conclusion

In this paper, we examined the interplay between public and private provision of education. Using a large public school construction initiative in the Dominican Republic, we found that increased public provision crowded out part of the private sector while also exerting competitive pressure that reduced private market power and increased quality. We specified and estimated a supply and demand model of education that enabled us to study how equilibrium effects scale with the amount of public provision, and how this relationship varies with the quality of the new public schools. In particular, we found that the optimal
level of public provision is potentially an intermediate amount, but that the optimal point
varies non-monotonically with the quality of the new public schools.

Future drafts will incorporate heterogeneous treatment effects in the event study anal-
ysis, extend the amount of preference heterogeneity in the demand model, and expand
the counterfactual analysis. We also hope to add investment in quality as an important
strategic choice that could explain some of the observed equilibrium effects.

A School Lotteries

Each lottery was divided into the 32 provinces that make up the country. Provinces had different numbers of construction lots depending on their size and existing school infrastructure. For example, in the first lottery round, Santo Domingo (the province home to the country’s capital city of the same name) included 43 lots while Dajabón included just three. In any given lottery round, applicants were only allowed to participate in a single province of their choosing.

For every lottery round, each of the 32 provinces held simultaneous lotteries. Applicants were required to attend the lottery in the province in which they participated. The lottery process worked as follows. Each applicant who fulfilled the minimum requirements received a lottery number that was posted online the day before the draw. The day of the lottery, all numbers were then placed in an urn and, for every lot, three applicants were randomly drawn. The applicant holding the first drawn number was assigned as the winner of that lot and their number was removed from the urn. In case the winner proved unable to complete the contract, the applicants holding the numbers drawn second and third were assigned as possible replacements. The backups’ numbers were then put back inside the urn. As a result, lottery winners could obtain a contract for at most one school, while those in second and third places could still compete for another contract.

Table 6 provides a summary of each lottery round, including its budget, the number of lots it included, and the date on which it was held. The first lottery took place in November 2012, and the last one in December 2014. Each lottery round included between 100 lots – for the QEC round – and 548 lots and had average contract values ranging between 26 and 58 million Dominican pesos (or 0.602 and 1.347 million USD). The number of lots included in each lottery increased in later rounds as did the size of the contracts, reflecting the fact that that later lotteries included more contracts for the construction – as opposed to renovation – of classrooms.

Table 7 presents the number of participants and winners per lottery round. Naturally, the number of winners in each lottery round is the same as the number of lots, while the number of second and third places is smaller as any given participant could be drawn in second or third place for multiple lots. Across all lottery rounds, the majority of applicants

Notes: Add Notes

Given the random nature of the assignment, we observe a similar distribution of firms and individuals among winners. Although winners were excluded from draws for subsequent lots, they were still able to participate in future lottery rounds as long as they had delivered the contracted classrooms and terminated their previous contract beforehand. The probability of participating in another lottery round conditional on having participated at all varies between 70 and 75 percent.
B Data preparation for demand estimations

This appendix contains:

- An explanation of the steps followed in the delimitation of the schooling markets’ boundaries
- A description of the data build that combines census and Prosoli data to characterize households in markets

B.1 Market construction - Standard methodology overview

The standard set of steps to define a schooling market \( m \) is as follows:

1. Geographic boundaries \( B^m \) (a polygon).
2. A set of schools \( F^m \) that operate within at any point in time.
3. A set of \( S^m \) students of \( K \) observable types that live inside the market.
4. A distribution of student types across markets. The distribution is described by \( \Pi^m \) which is a vector of length \( K \) containing the shares of each type of student in the market \( m \). We have that \( \sum_k^K \Pi^m_k = 1 \) for each market \( m \) and \( \sum_k^K S^m_k = S^m \).
5. A set of \( N^m \) nodes spread evenly within the boundaries of the market that describe where students are located.
6. A distribution of student types across nodes within each market. This distribution is described by \( w^m_k \) which is a vector of length \( N^m \) containing the share of students of type \( k \) of the market \( m \) that are located at each node \( n \). We have that \( \sum_n^{N^m} w_{nk} = 1 \) and \( \sum_k^K \sum_n^{N^m} w_{nk} \Pi_k S^m_k = S^m \).

B.2 Geographic Boundaries (\( B^m \))

The census map data in the Dominican Republic is divided into Regions (10), Provinces (32), Municipalities (155), Districts (386), Sections (1,565), Neighborhoods (12,565), Polygons, Supervision Areas, and Segments. We use neighborhoods (BPs hereafter, for Barrio/Paraje) as the building blocks of our markets since they are small enough to be entirely
classified as either urban or rural. The average BP has an area of 3.8 $km^2$ and is populated by 250 households.

The first step is to select the urban BPs. Using the census’ classification of urban areas yielded 2,620 of them as a starting point. However, overlaying the roads map on top suggested that this definition was too restrictive as it was ignoring a significant portion of urban sprawl. Therefore, we extended the definition so that the starting point to build the markets would be the set of BPs classified as urban in the census plus any BP with a population density of over 1000 inhabitants per $km^2$. Figure B.1 highlights all the selected urban BPs (before joining them to generate markets). The mean area of the selected neighborhoods is 0.7 $km^2$.

Then, we proceeded to join all urban neighborhoods that were separated by 2 $km$ or less at their closest distance. This resulted in 302 non-overlapping markets that could comprise a single neighborhood (isolated urban areas) or any number up to 272 neighborhoods. Around each market, we added a 1 km buffer. Figure ?? shows as an example the market of Santo Domingo.

### B.3 Nodes within markets ($N^m$)

Once the market boundaries have been defined, we overlay a grid of squared nodes on top to have a standardized geographic unit that is consistent over time. The nodes are $400m \times 400m$ and thus have an area of 0.16$km^2$. Figure B.3 shows the same market from Figure ??, divided into homogeneous nodes. It also shows that these nodes allow for a detailed characterization of demographic heterogeneity.

### B.4 Construction of $\Pi^m$ (Market-level data) and $w^m_k$ (Node-level Data)

The population of the markets is binned into 4 groups based on two characteristics (highest educational level attained, poverty status) that may predict heterogeneous responses to the policy in place. The types are defined as:

- Type 1: Less than secondary education and poor
- Type 2: Less than secondary education and not poor
Figure B.1: Urban Barrios/Parajes

- Type 3: Secondary or above and poor
- Type 4: Secondary or above and not poor

For each market, we can recover \( \Pi \) and \( w^m_k \) by combining two sources of microdata, and making some assumptions. Here we describe these data and explain the specific steps we followed.

Step 1: Clean census data and get the number of adults over 25 by Segmento. Break this number down into \( N \) of adults that finished any of the 3 educational levels specified in the types of “Option 1”. Output: Segment-level dataset with ONE code, ONE name of barrio, number of adults in each of the 3 education categories (*).

Step 2: Clean Prosoli data to get the \( N \) of poor adults (over 25) by Barrio/Paraje. I get 10,268 BPs. Output: Barrio-level poor counts dataset with prosoli name

Step 3: Fuzzy merge Barrio-level prosoli data to MapParajes (ONE registry of Barrios).
So now I have the barrio-level dataset from step 2, with ONE code. *Output: Barrio-level poor counts dataset with ONE code*

Step 5: For each barrio, spread the number of poor people uniformly among the segmentos that intersect with it, using areas of intersection as weights. *Output: Segment-level poor counts dataset with ONE code*

Step 6: Merge output from step 5 to output from step 1. Now we have poor counts and educational level counts by segmento. We assume independent marginal distributions and simulate the joint distribution.

Step 7: Aggregate into homogeneous nodes, again using areas of intersection as weights and assuming the population is uniformly distributed.

---

30One detail to consider is that the Census and Prosoli are 8 years apart. Therefore, all N from the Census data were adjusted to account for population growth using the average rate for the past 8 years in the following way: $x = x \times (1.015)^8$. A pending task is to look for growth rates for specific areas, as population growth most likely is not uniform. However, overcoming this limitation should be straightforward once we access the 2020 census.
